3 tidyverse

The tidyverse is a suite of packages released by RStudio that work very well together ("verse") to make data analysis run smoothly ("tidy"). It's also a package in R that loads all the packages in the tidyverse at once.

library(tidyverse)

You actually already know one member of the tidyverse – ggplot2! We will highlight three more packages in the tidyverse for data analysis.

Data Analysis Pipeline

Adapted from R for Data Science, Wickham & Grolemund (2017)

3.1 readr

The first step in (almost) any data analysis task is reading data into R. Data can take many formats, but we will focus on text files.

But what about .xlsx??

File extensions .xls and .xlsx are proprietary Excel formats/ These are binary files (meaning if you open one outside of Excel it will not be human readable). An alternable for rectangular data is a .csv.

.csv is an extension for *comma separated value* files. They are text files – directly readable – where each column is separated by a comma and each row a new line.

Rank, Major_code, Major, Total, Men, Women, Major_category, ShareWomen 1,2419, PETROLEUM ENGINEERING, 2339, 2057, 282, Engineering, 0.120564344

3.1 readr 45

```
2,2416,MINING AND MINERAL ENGINEERING,756,679,77,Engineering,0.101851852
```

.tsv is an extension for *tab separated value* files. These are also text files, but the columns are separated by tabs instead of commas. Sometimes these will be .txt extension files.

```
Major code
Rank
                       Major
                                Total
                                          Men
                                                  Women
                                                           Major_category
                                                                              ShareWomen

                                                2057
                                                         282
                                                                Engineering
                                                                                0.120564344
2
     2416
             MINING AND MINERAL ENGINEERING
                                                  756
                                                         679
                                                                77
                                                                       Engineering
                                                                                       0.10185
```

The package readr provides a fast and friendly way to ready rectangular text data into R.

Here is an example csv file from fivethirtyeight.com on how to choose your college major (https://fivethirtyeight.com/features/the-economic-guide-to-picking-a-college-major/).

```
## Parsed with column specification:
## cols(
## .default = col_double(),
## Major = col_character(),
## Major_category = col_character()
## )
```

See spec(...) for full column specifications.

read_csv() is just one way to read a file using the readr package.

- read_delim(): the most generic function. Use the delim argument to read a file with any type of delimiter
- read_tsv(): read tab separated files
- read_lines(): read a file into a vector that has one element per line of the file
- read file(): read a file into a single character element
- read table(): read a file separated by space

3 tidyverse

Your Turn

 $1. \ Read \ the \ NFL \ salaries \ dataset \ from \ \underline{https://raw.githubusercontent.com/ada-love-craft/ProcessingSketches/master/Bits\%20 and \%20 Pieces/Football_Stuff/data/nfl-salaries.tsv \ into \ R.$

- 2. What is the highest NFL salary in this dataset? Who is the highest paid player?
- 3. Make a histogram and describe the distribution of NFL salaries.

$3.2 \, dplyr$

We almost never will read in data and have it in exactly the right form for visualizing and modeling. Often we need to create variable or summaries.

To facilitate easy transformation of data, we're going to learn how to use the dplyr package. dplyr uses 6 main verbs, which correspond to some main tasks we may want to perform in an analysis.

We will do this with the recent_grads data from fivethiryeight.com we just read into R using readr.

3.2.1 %>%

Before we get into the verbs in dplyr, I want to introduce a new paradigm. All of the functions in the tidyverse are structured such that the first argument is a data frame and they also return a data frame. This allows for efficient use of the pipe operator %>% (pronounce this as "then").

```
a %>% b()
```

Taked the result on the left and passes it to the first argument on the right. This is equivalent to

```
b(a)
```

This is useful when we want to chain together many operations in an analysis.

$3.2.2 \, filter()$

filter() lets us subset observations based on their values. This is similar to using [] to subset a data frame, but simpler.

The first argument is the name of the data frame. The second and subsequent arguments are the expressions that filter the data frame.

Let's subset the recent_grad data set to focus on Statistics majors.

```
recent_grads %>% filter(Major == "STATISTICS AND DECISION SCIENCE")
```

```
## # A tibble: 1 x 21
##
      Rank Major_code Major Total
                                    Men Women Major_category ShareWomen
##
                <dbl> <chr> <dbl> <dbl> <dbl> <chr>
                                                                    <dbl>
## 1
        47
                 3702 STAT... 6251 2960 3291 Computers & M...
                                                                   0.526
## # ... with 13 more variables: Sample size <dbl>, Employed <dbl>,
       Full_time <dbl>, Part_time <dbl>, Full_time_year_round <dbl>,
## #
## #
       Unemployed <dbl>, Unemployment rate <dbl>, Median <dbl>, P25th <dbl>,
       P75th <dbl>, College_jobs <dbl>, Non_college_jobs <dbl>,
## #
## #
       Low_wage_jobs <dbl>
```

Alternatively, we could look at all Majors in the same category, "Computers & Mathematics", for comparison.

```
recent_grads %>% filter(Major_category == "Computers & Mathematics")
```

```
## # A tibble: 11 x 21

```

Notice we are using %>% to pass the data frame to the first argument in filter() and we do not need to use recent_grads\$Colum Name to subset our data.

dplyr functions never modify their inputs, so if we need to save the result, we have to do it using <-.

Everything we've already learned about logicals and comparisons comes in handy here, since the second argument of filter() is a comparitor expression telling dplyr what rows we care about.

3.2.3 arrange()

##

<dbl>

arrange() works similarly to filter() except that it changes the order of rows rather than subsetting. Again, the first parameter is a data frame and the additional parameters are a set of column names to order by.

```
math_grads %>% arrange(ShareWomen)

## # A tibble: 11 x 21
```

```
## # A tibble: 11 x 21
##
       Rank Major_code Major

3.2.4 select()

Sometimes we have data sets with a ton of variables and often we want to narrow down the ones that we actually care about. select() allows us to do this based on the names of the variables.

```
math_grads %>% select(Major, ShareWomen, Total, Full_time, P75th)
```

```
## # A tibble: 11 x 5
##
      Major
                                               ShareWomen
                                                           Total Full_time P75th

```

We can also use

- : to select all columns between two columns
- - to select all columns except those specified

- starts_with("abc") matches names that begin with "abc"
- ends_with("xyz") matches names that end with "xyz"
- contains("ijk") matches names that contain "ijk"
- everything() mathes all columns

```
math_grads %>% select(Major, College_jobs:Low_wage_jobs)
```

```

3.2.5 mutate()

Besides selecting sets of existing columns, we can also add new columns that are functions of existing columns with mutate(). mutate() always adds new columns at the end of the data frame.

```
math_grads %>% mutate(Full_time_rate = Full_time_year_round/Total)
```

```

3.2.6 summarise()

The last major verb is summarise(). It collapses a data frame to a single row based on a summary function.

A useful summary function is a count (n()), or a count of non-missing values (sum(!is.na())).

$3.2.7 \text{ group_by()}$

summarise() is not super useful unless we pair it with group_by(). This changes the unit of analysis from the complete dataset to individual groups. Then, when we use the dplyr verbs on a grouped data frame they'll be automatically applied "by group".

```
recent_grads %>%
  group_by(Major_category) %>%
  summarise(mean_major_size = mean(Total, na.rm = TRUE)) %>%
  arrange(desc(mean_major_size))
```

```
## # A tibble: 16 x 2

                                                    8402.
```

We can group by multiple variables and if we need to remove grouping, and return to operations on ungrouped data, we use ungroup().

Grouping is also useful for arrange() and mutate() within groups.

Your Turn

Using the NFL salaries from $\frac{https://raw.githubusercontent.com/ada-lovecraft/Process-ingSketches/master/Bits%20and%20Pieces/Football_Stuff/data/nfl-salaries.tsv that you loaded into R in the previous your turn, perform the following.$

- 1. What is the team with the highest paid roster?
- 2. What are the top 5 paid players?
- 3. What is the highest paid position on average? the lowest? the most variable?

3.3 tidyr

"Happy families are all alike; every unhappy family is unhappy in its own way." — Leo Tolstoy

"Tidy datasets are all alike, but every messy dataset is messy in its own way." — Hadley Wickham

Tidy data is an organization strategy for data that makes it easier to work with, analyze, and visualize. tidyr is a package that can help us tidy our data in a less painful way.

The following all contain the same data, but show different levels of "tidiness".

table3

spread across two data frames table4a

table4b

While these are all representations of the same underlying data, they are not equally easy to use.

There are three interrelated rules which make a dataset tidy:

1. Each variable must have its own column.

- 2. Each observation must have its own row.
- 3. Each value must have its own cell.

In the above example,

table2 isn't tidy because each variable doesn't have its own column.

table3 isn't tidy because each value doesn't have its own cell.

table4a and table4b aren't tidy because each observation doesn't have its own row.

table1 is tidy!

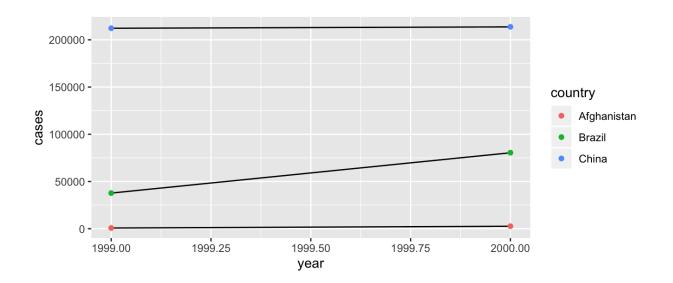

Being tidy with our data is useful because it's a consistent set of rules to follow for working with data and because it allows R to be efficient.

```
# Compute rate per 10,000
table1 %>%
  mutate(rate = cases / population * 10000)
```

```
## # A tibble: 6 x 5
##
    country year cases population rate
               <int> <int>
##
    <chr>
                                <int> <dbl>
## 1 Afghanistan 1999
                        745
                             19987071 0.373
## 2 Afghanistan 2000
                       2666 20595360 1.29
## 3 Brazil
                1999 37737 172006362 2.19
                2000 80488 174504898 4.61
## 4 Brazil
## 5 China
                1999 212258 1272915272 1.67
## 6 China
                2000 213766 1280428583 1.67
```

```
# Visualize cases over time
library(ggplot2)
ggplot(table1, aes(year, cases)) +
  geom_line(aes(group = country)) +
  geom_point(aes(colour = country))
```

3.3 tidyr 59

3.3.1 Pivoting

Unfortunately, most of the data you will find in the "wild" is not tidy. So, we need tools to help us tidy unruly data.

The main tools in tidyr are the ideas of pivot_longer() and pivot_wider(). As the names imply, pivot_longer() "lengthens" our data, increasing the number of rows and decreasing the number of columns. pivot_wider does the opposite, increasing the number of columns and decreasing the number of rows.

These two functions resolve one of two common problems:

- 1. One variable might be spread across multiple columns. (pivot_longer())
- 2. One observation might be scattered across multiple rows. (pivot_wider())

A common issue with data is when values are used as column names.

table4a

We can fix this using pivot_longer().

3 tidyverse

```
table4a %>%
  pivot_longer(-country, names_to = "year", values_to = "cases")
```

```
## # A tibble: 6 x 3
    country
                year
                       cases
##
    <chr>
                <chr> <int>
## 1 Afghanistan 1999
                        745
## 2 Afghanistan 2000
                        2666
## 3 Brazil
                1999
                       37737
## 4 Brazil
                2000
                     80488
                1999 212258
## 5 China
## 6 China
                2000 213766
```

Notice we specified with columns we wanted to consolidate by telling the function the column we *didn't* want to change (-country). We can use the dplyr::select() syntax here for specifying the columns to pivot.

We can do the same thing with table4b and then join the databases together by specifying unique identifying attributes.

```
## # A tibble: 6 x 4
               year
                      cases population
    country
##
    <chr>
               <chr> <int>
                                <int>
                        745
## 1 Afghanistan 1999
                             19987071
## 2 Afghanistan 2000
                       2666
                            20595360
## 3 Brazil
               1999 37737 172006362
## 4 Brazil
               2000 80488 174504898
## 5 China
               1999 212258 1272915272
## 6 China
               2000 213766 1280428583
```

Joining, by = c("country", "year")

If, instead, variables don't have their own column, we can pivot_wider().

```
table2
```

3.3 tidyr 61

```
## # A tibble: 12 x 4
##
     country
                 year type
                                       count
##
      <chr>
                 <int> <chr>
                                       <int>
## 1 Afghanistan 1999 cases
                                         745
   2 Afghanistan
                  1999 population

                                      213766
## 12 China
                  2000 population 1280428583
```

```
table2 %>%
  pivot_wider(names_from = type, values_from = count)
```

```
## # A tibble: 6 x 4
    country
            year cases population
##
     <chr>
                <int> <int>
                                 <int>
## 1 Afghanistan 1999
                         745
                              19987071
## 2 Afghanistan 2000
                        2666
                              20595360
## 3 Brazil
                 1999 37737 172006362
## 4 Brazil
                 2000 80488 174504898
## 5 China
                1999 212258 1272915272
## 6 China
                 2000 213766 1280428583
```

3.3.2 Separating and Uniting

So far we have tidied table2 and table4a and table4b, but what about table3?

table3

```
## 5 China 1999 212258/1272915272
## 6 China 2000 213766/1280428583
```

We need to split the rate column into the cases and population columns so that each value has its own cell. The function we will use is separate(). We need to specify the column, the value to split on ("/"), and the names of the new coumns.

```
table3 %>%
  separate(rate, into = c("cases", "population"), sep = "/")
```

```
## # A tibble: 6 x 4
##
     country
                year cases
                              population
##
     <chr>
                 <int> <chr>
                              <chr>>
## 1 Afghanistan 1999 745
                              19987071
## 2 Afghanistan 2000 2666
                              20595360
## 3 Brazil
                 1999 37737
                              172006362
## 4 Brazil
                 2000 80488
                              174504898
## 5 China
                 1999 212258 1272915272
## 6 China
                 2000 213766 1280428583
```

By default, separate() will split values wherever it sees a character that isn't a number or letter.

unite() is the opposite of separate() - it combines multiple columns into a single
column.

Your Turn

1. Is the NFL salaries from https://raw.githubusercontent.com/ada-lovecraft/ProcessingSketches/master/Bits%20and%20Pieces/Football_Stuff/data/nfl-salaries.tsv that you loaded into R in a previous your turn tidy? Why or why not?

- 2. There is a data set in tidyr called world_bank_pop that contains information about population from the World Bank (https://data.worldbank.org/). Why is this data not tidy? You may want to read more about the data to answer (?world_bank_pop).
- 3. Use functions in tidyr to turn this into a tidy form.
